Background

Intergluteal lesions are associated with Hidradenitis Suppurativa (HS) in up to 27% of cases and there are accumulating evidences suggesting that pilonidal sinus disease (PSD) may be a variant form of Hidradenitis suppurativa1. The microbiology of HS lesions has been recently characterized, showing that a specific anaerobic flora is associated with a vast majority of HS lesions 2,3.

Aim of the study

To characterize the microbiology of suppurative PSD compared to HS gluteal lesions.

Methods

Cross-sectional study realised in Paris, France. We compared the microbiology of 12 suppurative PSD to that of 17 intergluteal HS lesions, of 44 clinically non affected HS gluteal skinfold and of 16 in healthy subjects. Patients with PSD had no other skin lesions and were recruited at the Saint-Joseph Hospital Leopold Bellan clinic, a surgical specialized center in Paris. HS subjects and controls were recruited at the Dermatology Unit of the Centre Médical and at the ICARe8 Platform of the Institut Pasteur, respectively.

All sample were obtained by pus or surface skin swabbing, except for PSD samples that were obtained during surgery. No patients received antibiotics during the month preceding inclusion. All samples were analysed by prolonged bacterial cultures. 16S ribosomal RNA gene amplicon sequencing was performed on 50 randomly selected samples including 6 PSD samples.

Results

Bacterial culture results (Fig 1). The microbiology of PSD was typical of anaerobic abscesses, consisting in strict anaerobes (40%), Actinomyces spp (18%), pyogenic streptococci (9%), associated with Corynebacterium spp (21%). This microbiological profile was similar to that of HS gluteal lesions.

16S ribosomal gene amplicon sequencing sequencing results (Fig 2 and 3). Corynebacterium, Staphyloccocus, Anaerococcus and Finegaldia were the most abundant genera in unaffected gluteal HS skinfolds and controls. The microbiome of PSDs and HS gluteal lesions was predominantly anaerobic, Prevotella, Porphyromonas, Fusobacterium, and Peptoniphilus being the main taxa. The relative abundance of skin commensals (Staphyloccocus and Corynebacterium) was higher in HS lesions skin samples, probably due to the sampling method.

Discussion and conclusion

The microbiology of suppurative PSD is typical of polymicrobial anaerobic abscesses and similar to that of gluteal HS lesions. As previously reported in HS 2,3, Prevotella and Porphyromonas are the main anaerobic taxa, establishing a new link between the two diseases and suggesting common pathophysiologic features.
