Abstract

The morphological description of fractal agglomerates is generally reduced to only two parameters, namely the mass fractal dimension and its prefactor. In the most evolved approaches, a stretching exponent is also introduced, while a packing factor is preferred to the fractal prefactor. In any case, the current analytical description of agglomerates morphology is accurate only for sufficiently large agglomerates, which is due to the limited spatial extension of the clusters that are actually "quasi-fractal". In the present study, a cutoff function of the pair correlation function is considered for both larger and smaller scales. This enables a more accurate morphological description valid for any cluster size is to be given taking into account the polydispersity of the primary spheres. This new analytical morphological description relying on 5 parameters, is presented here for the first time. The physical range covered by these morphological parameters is determined based on virtually generated Diffusion Limited Cluster Agglomeration. Finally, the model is used to express the fractal prefactor and structure factors and their dependence on agglomerates size and morphological parameters is investigated.

Keywords: Fractal Dimension; fractal prefactor; soot; SAXS

Nomenclature

 $\beta,\beta_0,\beta_\infty$ Stretching exponent, at small and large scales. [-]

- Γ The gamma function.
- Λ An integral. [-]
- λ Wavelength. [m]
- $\overrightarrow{d_{ij}}$ Distance between centers of spheres i and j. [m]

 \overrightarrow{q} Scattering wave vector. $[m^{-1}]$

- $\overrightarrow{r}, \overrightarrow{u}$ Position vectors. [m]
- θ Scattering angle. [rad]
- φ Packing factor. [-]
- $\xi,\xi_0,\xi_\infty\,$ Equivalent spatial extension length scale, small and large scales size parameters. [m]
- a Characteristic primary sphere radius. [m]
- A, A_{pp}, A_{agg} Pair correlation function, for primary sphere self-intersection, for different primary spheres intersection. $[m^3]$
- C Constant of proportionality. $\left[m^{6-D_f}\right]$
- D_f, D_{fi}, D_{fp} Particle fractal dimension, individual particle and population based dimension. [-]
- f_{pp} The probability density function of the primary spheres. $[m^{-1}]$
- $k_f, k_{fi}, k_{fi,\infty}, k_{fp}$ Particle's fractal prefactor, individual one, individual one for infinitely large agglomerates and population based one. [-3]
- $n(\vec{r})$ Indicator of presence of material. [-]
- N_p Number of primary spheres per agglomerate. [-]

- r Radial distance. [m]
- R_g Radius of gyration. [m]
- R_p, R_{pi}, R_{pv} Primary sphere radius, for the *i*th sphere, volume equivalent primary sphere. [m]
- S, S_{∞} Structure factor, structure factor for infinitely large agglomerates. [-]
- V, V_p, V_a Volume of intersection between two spheres, volume of a primary sphere and of the agglomerate. $[m^3]$

Highlights

- An analytical form of the pair correlation function is proposed.
- Morphological description independent of agglomerates size.
- Fractal prefactor and structure factor as a function of size.

Graphical Abstract

1 1. Introduction

Agglomeration is a phenomenon observed for both aerosols and colloids and of particular importance in nanoscience. Agglomerates thus generated often exhibit a ramified structure due to the random nature of their Brownian movement. In many cases, an empirical power-law relationship between the agglomerate mass and size is observed such as the very commonly used fractal law Meakin (1991); Jullien (1992); Bushell et al. (2002). When this is plotted in a normalised log-log graph, the slope and the intercept are related to the population based mass fractal dimension D_{fp} and prefactor k_{fp} respectively:

$$N_p = k_{fp} \left(\frac{R_g}{a}\right)^{D_{fp}} \tag{1}$$

where N_p is the number of primary spheres, R_g the radius of gyration of a given agglomerate and a is a characteristic primary sphere radius. This equation is very useful in many applications and extremely popular due to its simplicity. It is well accepted that the mass fractal dimension is related to the agglomeration regime (typically $D_{fp} \simeq 1.78$ in diffusion limited regimes and up to 1.91 in ballistic agglomeration) Meakin (1999), with a high value for more "compact" particles. Much less attention has been paid to k_{fp} , that is shown to be related to a greater dispersion $(k_{fp} \simeq 1 \text{ in simulations})$ and up to 5 in experimental observations Wu and Friedlander (1993); Lapuerta et al. (2010)). Moreover, its physical meaning is less clear, even if different studies have been conducted with the aim of exhibiting a relationship between k_{fp} and D_{fp} Sorensen and Roberts (1997); Ehrl et al. (2009) or between k_{fp} and N_p Lapuerta et al. (2010); Gmachowski (2002). Some authors Ehrl et al. (2009); Lazzari et al. (2016); Isella and Drossinos (2010); Lattuada et al. (2003) have shown that an agglomerate needs to be constituted of at least 15 to 30 primary spheres before k_{fp} arrives at an asymptotic behaviour, which highlights the limited validity of the fractal law Eq. 1 for smaller clusters. Still, in many cases, the fractal law is used for clusters with a limited number of primary spheres Köylü et al. (1997); Lee et al. (2000); Wentzel et al. (2003); Cortés et al. (2018). For example, for soot particles, most of the particles contain nearly 60 primary spheres in stationary diffusion flames Kholghy et al. (2013) or even less for shorter flame residence time Cortés et al. (2018); Bladh et al. (2011); Gigone et al. (2019); Altenhoff et al. (2019). For such applications, the question arises on the validity of the use of the fractal law for Scanning/Transmission Electron Microscopy

(SEM/TEM) analysis Wozniak et al. (2012) as well as for mobility diameter interpretation Betrancourt et al. (2017); Tang et al. (2017) or X-ray or visible light scattering diffraction pattern analysis Yon et al. (2018); Bouvier et al. (2019); Sorensen et al. (1995). For instance it is not known, whether the size dependence of the fractal prefactor needs to be considered, and whether one should extend current light-agglomerate interaction models such as the Rayleigh Debye Gans theory for Fractal Agglomerates (RDG-FA) in the visible domain Sorensen (2001) or the Beaucage analysis for Small Angle X-ray (SAXS) analysis Beaucage (1995) for quasi-fractal agglomerates. In order to answer these questions, it is necessary to characterize the morphology of individual agglomerates, and the most suitable tool is probably the pair correlation function:

$$A\left(\overrightarrow{r}\right) = \int_{\overrightarrow{u}=\overrightarrow{0}}^{\infty} n\left(\overrightarrow{r}-\overrightarrow{u}\right) n\left(\overrightarrow{u}\right) d\overrightarrow{u}$$
(2)

where $n(\vec{r})$ is 1 if \vec{r} points towards the material and 0 otherwise. When A is averaged over the agglomerate orientations, the result becomes a smooth function of r. It can be demonstrated that the agglomerate volume V_a and the radius of gyration R_g can be determined based on a knowledge of A(r) (see Appendix of Sorensen (2001) and ref. Nicolai et al. (1994)):

$$V_a^2 = \int 4\pi r^2 A(r) \, dr \tag{3}$$

$$R_g^2 = \frac{1}{2} \frac{\int_{r=0}^{\infty} r^4 A(r) \, dr}{\int_{r=0}^{\infty} r^2 A(r) \, dr} \tag{4}$$

In the case of an ideal fractal cluster, the average pair correlation function should exhibit a power-law behaviour $(A(r) \propto r^{D_{fi}-3})$ whose slope in a log-log plot is related to the cluster individual fractal dimension D_{fi} . Theoretically, the average of D_{fi} over the entire population of particles should be D_{fp} . However, real agglomerates have a finite size and a cutoff function needs to be added Sorensen (2001); Cai et al. (1995); Rottereau et al. (2004); Lin et al. (1990); Sorensen et al. (1992a):

$$A(r) \propto r^{D_{fi}-3} \exp\left(-(r/\xi)^{\beta}\right) \tag{5}$$

The cutoff is driven by a spatial extension ξ and a stretching exponent β Nicolai et al. (1994). The latter parameter plays an important role on the scattering properties Sorensen (2001) and, as demonstrated by Heinson et al. (2012), is correlated with the particle anisotropy. The same authors have introduced a packing factor φ , which expresses the local arrangement of neighbouring spheres and ensures mass conservation (respect of Eq. 3):

$$A(r) = \frac{\varphi D_{fi}}{4\pi R_p^{D_{fi}}} r^{D_{fi}-3} \exp\left(-(r/\xi)^{\beta}\right) \tag{6}$$

with R_p the monomer primary sphere. By applying this last expression for the pair correlation function in Eq. 4 and the corresponding expression for the radius of gyration into Eq. 1, Heinson et al. (2012) have shown the link between the fractal prefactor and the three parameters D_{fi} , φ and β for large agglomerates,

$$k_{fi,\infty} = \left[\frac{2\Gamma(D_{fi}/\beta)}{\Gamma((D_{fi}+2)/\beta)}\right]^{\frac{D_{fi}}{2}} \frac{\varphi D_{fi}\Gamma(D_{fi}/\beta)}{\beta}$$
(7)

The authors introduce an individual prefactor k_{fi} based on the underlying 10 assumption that the entire population of an agglomerate has identical φ , 11 $D_{fi} = D_{fp}$ and β parameters. Equation 7 highlights the complexity of the 12 prefactor due to its dependence on these three parameters, which partly 13 explains the dispersity of the reported values of k_{fp} in the literature even 14 without considering primary sphere overlapping Brasil et al. (1999). To the 15 authors' knowledge, until now the work reported by Heinson et al. (2012)16 is the most up to date and relevant on this subject. However, it is only 17 valid for agglomerates consisting of monodisperse monomers whose number 18 is large enough to ensure the validity of Eq.6 i.e. neglecting smaller scales. 19 Therefore, Eq.7 should not be considered for clusters for which N_p is less 20 than approximately 30. 21

In addition to the morphological signature embedded in the pair correlation function, one particularly interesting feature of this function is that its normalized Fourier transform corresponds to the particle structure factor, i.e. the description of its light scattering pattern Debye et al. (1957):

$$S(\overrightarrow{q}) = \frac{\int A(\overrightarrow{r}) \exp(i\overrightarrow{q}\cdot\overrightarrow{r})d\overrightarrow{r}}{\int A(\overrightarrow{r})d\overrightarrow{r}}$$
(8)

where \overrightarrow{q} is the scattering wave vector whose norm is $q = \frac{4\pi}{\lambda} \sin(\theta/2)$. By definition, the structure factor is 1 in the case of forward scattering $(\theta = 0)$. S(q) is thus a modulating factor for the forward light scattering intensity

enabling a description to be given of the impact of the light collection an-25 gle θ Oltmann et al. (2010); Kempema and Long (2016); Bushell and Amal 26 (2000) and wavelength λ Lefevre et al. (2019); Bouvier et al. (2019) on the 27 light scattering signal. The main assumption is that each constituent of the 28 particle individually scatters the incident light without any disturbance by 29 other components. This is valid in the Rayleigh scattering regime (particles 30 small compared to the wavelength) and if the refractive index is close to 1 31 (X ray scattering, cf SAXS, neutron scattering, etc.) Zhao et al. (2007). The 32 modelling of the structure factor thus provides a quantitative interpretation 33 of light scattering patterns in terms of particle size and shape. For agglom-34 erates, this function has been used to provide the most simple analytical 35 expressions of the structure factor possible. While the community concerned 36 by visible light often employs the RDG-FA, see Refs. Sorensen (2001)), the 37 community working with X rays or short wavelengths as in SAXS, more usu-38 ally uses the Beaucage model Beaucage (1995); Beaucage et al. (2004). In 39 any case, those two models also consider clusters large enough to express 40 their fractal signature. 41

For these reasons, Lattuada et al. (2003) focused on the pair correlation 42 of agglomerates with a number of primary spheres below 100. They observed 43 a transition regime at smaller scales that was empirically modeled by a new 44 power law regime. However, the primary sphere volume was not considered 45 in their numerical determination of the pair correlation function and the 46 parameters of their model do not allow a physical interpretation of the phe-47 nomena involved to be made. Therefore, the purpose of the present study 48 is to pursue that investigation by improving the numerical computation of 49 the pair correlation and its modelling by considering the primary sphere vol-50 ume and a new cutoff function for smaller scales. Another aim is to consider 51 the effect of primary sphere polydispersity. Moreover, the study will show 52 that a finer description of the pair correlation function at both small and 53 large scales enables the validity of the fractal law and structure factor to be 54 extended to all agglomerate sizes. 55

⁵⁶ 2. Proposed model

57 2.1. Pair correlation

As explained in introduction, the validity of the fractal law and of the structure factor for smaller particles is limited by the fact that the pair correlation function behaviour at small scales is not taken into account, most certainly due to the current numerical way of computing A(r) (discussed later in section 3.1. In fact, the modelling of the pair correlation function can be decomposed into two distinct terms A_{pp} and A_{agg} :

$$A(\overrightarrow{r}) = \underbrace{\sum_{i=1}^{N_p} V(R_{pi}, R_{pi}, \overrightarrow{r})}_{A_{pp}} + \underbrace{\sum_{i=1}^{N_p} \sum_{j=1 \& j \neq i}^{N_p} V(R_{pi}, R_{pj}, \overrightarrow{d_{ij}})}_{A_{agg}}$$
(9)

where $V(R_{pi}, R_{pj}, \overrightarrow{d_{ij}})$ represents the interception volume between two spheres of radius R_{pi} and R_{pj} respectively, for which the distance between respective centers is d_{ij} . The first term A_{pp} represents the contribution of the intersection of spheres with themselves whereas A_{agg} represents the interception between different spheres. For agglomerates made of point contact spheres, A_{pp} can be simplified to:

$$A_{pp}(r) = \sum_{i=1}^{N_p} V_{pi}\left(1 + \frac{r}{4R_{pi}}\right) \left(1 - \frac{r}{2R_{pi}}\right)^2, \qquad r \in [0, 2R_{pi}]$$
(10)

where V_{pi} is the volume of the *i*th monomer. Since particle self interaction (A_{pp}) is now considered for short scales, a cutoff must also be considered for smaller scales in the expression for A_{agg} . Indeed, for just touching spheres, A_{agg} is supposed to tend towards 0 when $r \to 0$. Therefore, a cutoff function for small scales, similar to those currently used at larger scales, is added to the model:

$$A_{agg}(r) \propto \left(1 - \exp\left(-(r/\xi_0)^{\beta_0}\right)\right) r^{D_{fi}-3} \exp\left(-(r/\xi_\infty)^{\beta_\infty}\right)$$
(11)

In this equation, ξ_0 and ξ_∞ refer to the smaller and larger length scales respectively and β_0 and β_∞ to the stretching exponents relative to smaller and larger length scales respectively. In order to reduce the number of parameters, the following assumption, justified later, will be used: $\beta_0 = \beta_\infty = \beta$. This hypothesis enables a simplification of Eq. 11 to be made, which becomes:

$$A_{agg}(r) = Cr^{D_{fi}-3} \left[\exp\left(-(r/\xi_{\infty})^{\beta}\right) - \exp\left(-(r/\xi)^{\beta}\right) \right]$$
(12)

where $\xi = \left[\xi_0^{-\beta} + \xi_\infty^{-\beta}\right]^{-1/\beta}$ and *C* is a proportionality constant. This form is of interest for the following analytical developments.

60 2.2. Volume and radius of gyration

Based on Eqs. 3, 10 and 12 , the agglomerate's volume V_a has to respect the following equation:

$$V_a = \frac{\overline{V_p^2}}{\overline{V_p}} + \frac{4\pi C}{\beta V_a} \Gamma\left(\frac{D_{fi}}{\beta}\right) \left(\xi_{\infty}^{D_{fi}} - \xi^{D_{fi}}\right)$$
(13)

where V_p is the volume of a primary sphere and $\overline{V_p^n}$ the moment of order n of the primary sphere volume. The specific case of an isolated sphere $(N_p = 1, V_a = V_p \text{ and } A_{agg} = 0)$ corresponds to $\xi_{\infty}^{D_{fi}} - \xi^{D_{fi}} = 0$, indicating $\xi_0 \rightarrow \infty$. For $N_p > 1, \xi_0$ quickly decreases to a scale representative of the primary sphere radius, as shown later.

Similarly, combining Eqs. 4 with 10 and 12 provides:

$$R_g^2 V_a = \frac{3}{5} \left(\frac{3}{4\pi}\right)^{2/3} \frac{\overline{V_p^{8/3}}}{\overline{V_p}} + \frac{2\pi C}{\beta V_a} \Gamma\left(\frac{D_{fi}+2}{\beta}\right) \left(\xi_{\infty}^{D_{fi}+2} - \xi^{D_{fi}+2}\right)$$
(14)

Finally, the constant $\frac{2\pi C}{\beta V_a}$ can be removed by substituting Eq. 13 into Eq. 14 in order to obtain the following expression for the radius of gyration:

$$R_g^2 = \frac{3}{5} \left(\frac{3}{4\pi}\right)^{2/3} \frac{\overline{V_p^{8/3}}}{\overline{V_p} V_a} + \left(1 - \frac{\overline{V_p^2}}{\overline{V_p} V_a}\right) \frac{\Gamma\left(\frac{D_{fi}+2}{\beta}\right)}{2\Gamma\left(\frac{D_{fi}}{\beta}\right)} \frac{\left(\xi_{\infty}^{D_{fi}+2} - \xi^{D_{fi}+2}\right)}{\left(\xi_{\infty}^{D_{fi}} - \xi^{D_{fi}}\right)} \quad (15)$$

66 2.3. Fractal prefactor

Knowing that, for point contact spheres, $N_p = \frac{V_a}{V_p}$, Eq. 15 can be used to express an individual prefactor based on Eq. 1. In the present study, the characteristic radius *a* is arbitrarily considered equal to the volume equivalent primary sphere radius $R_{pv} = \left(\frac{3\overline{V_p}}{4\pi}\right)^{1/3}$:

$$k_{fi} = \frac{V_a}{\overline{V_p}} \left[\frac{3}{5} \frac{\overline{V_p^{8/3}}}{\overline{V_p^{5/3}} V_a} + \left(1 - \frac{\overline{V_p^2}}{\overline{V_p} V_a} \right) \frac{\Gamma\left(\frac{D_{fi}+2}{\beta}\right)}{2R_{pv}^2 \Gamma\left(\frac{D_{fi}}{\beta}\right)} \frac{\left(\xi_{\infty}^{D_{fi}+2} - \xi^{D_{fi}+2}\right)}{\left(\xi_{\infty}^{D_{fi}} - \xi^{D_{fi}}\right)} \right]^{-\frac{D_{fi}}{2}}$$
(16)

67 2.4. Asymptotic cases $N_p = 1$ and infinitely large agglomerates

For an isolated sphere, the second term in brackets in Eq. 16 becomes zero reducing the equation to the well known expression $k_{fi,pp} = (3/5)^{-\frac{D_{fi}}{2}}$. For infinitely large clusters, the first term in brackets in Eq. 16 becomes negligible as well as $\xi^{D_{fi}+2}$ and $\xi^{D_{fi}}$ compared to $\xi^{D_{fi}+2}_{\infty}$ and $\xi^{D_{fi}}$ respectively. The same kind of simplification can be done with Eq. 13 for infinitely large clusters. By combining both simplified expressions for k_{fi} and V_a respectively, the analytical expression for the asymptotic individual prefactor becomes:

$$k_{fi,\infty} = \left[\frac{2\Gamma(D_{fi}/\beta)}{\Gamma((D_{fi}+2)/\beta)}\right]^{\frac{D_{fi}}{2}} \frac{3R_{pv}^{D_{fi}-3}C\Gamma(D_{fi}/\beta)}{\beta V_a}$$
(17)

This expression is similar to the result found by Heinson et al. (2012) recalled in Eq. 7. The comparison allows the constant C to be expressed as a function of the packing factor:

$$\frac{C}{V_a} = \frac{\varphi D_{fi}}{3R_{pv}^{D_{fi}-3}} \tag{18}$$

These results show that the generalized k_{fi} (Eq. 16) displays correct asymptotic behaviours. The constant C is proportional to the agglomerate volume but modulated by the packing factor, the primary sphere radius and the polydispersity. Finally, the same simplifications that are valid for infinitely large agglomerates can be made for the expression for the radius of gyration (Eq. 15), which leads to the following relation:

$$\frac{\xi_{\infty}}{R_g} = \left[\frac{2\Gamma\left(\frac{D_{fi}}{\beta}\right)}{\Gamma\left(\frac{D_{fi}+2}{\beta}\right)}\right]^{1/2} \tag{19}$$

This relation has already been proposed by Nicolai et al. (1994) in 1994. This ratio ξ_{∞}/R_g , is in agreement with the ratio of the cluster's maximum projected length and its gyration diameter determined numerically by Köylü et al. (1995) and Brasil et al. (1999). Thus, for large clusters, $2\xi_{\infty}$ can be seen as representative of the agglomerate's maximum projected length.

73 2.5. Structure factor

The newly developed model for the pair correlation function (Eq. 9, 10, 12) can now be incorporated into equation 8 in order to determine an analytical ⁷⁶ form of the structure factor for quasi-fractal agglomerates, which becomes as⁷⁷ follows:

$$S(q) = \frac{1}{N_p \overline{R_p^3}^2} \int_0^\infty 9R_p^6 \frac{[\sin(qR_p) - qR_p \cos(qR_p)]^2}{(qR_p)^6} f_{pp}(R_p) dR_p + \left(1 - \frac{1}{N_p} \frac{\overline{R_p^6}}{\overline{R_p^3}^2}\right) \frac{\beta}{q^{D_{fi}} \Gamma\left(\frac{D_{fi}}{\beta}\right)} \frac{\Lambda(q,\xi_\infty, D_{fi},\beta) - \Lambda(q,\xi, D_{fi},\beta)}{\xi_\infty^{D_{fi}} - \xi^{D_{fi}}}$$
(20)

where f_{pp} is the density probability function of the primary sphere radius, $\overline{R_p^n} = \int_0^\infty R_p^n f_{pp}(R_p) dR_p$ the primary sphere radius moment of order n and $\Lambda(q,\xi, D_{fi},\beta) = \int_0^\infty (qr)^{D_{fi}-1} e^{-\left(\frac{r}{\xi}\right)^\beta} \frac{\sin(qr)}{qr} d(qr).$ For isolated primary spheres, the second term of Eq. 20 vanishes and the

For isolated primary spheres, the second term of Eq. 20 vanishes and the first term simplifies to the well known expression for the structure factor for a distribution of spherical particles. At large q, this relation presents oscillations whose envelope has a slope of -4 when represented in a log-log plot (Porod's regime). One the other hand, for an infinitely large agglomerate, the first term becomes negligible as well as $\Lambda(q,\xi, D_{fi},\beta)$ compared to $\Lambda(q,\xi_{\infty}, D_{fi},\beta)$ and $\xi^{D_{fi}}$ compared to $\xi_{\infty}^{D_{fi}}$. Finally, by replacing ξ_{∞} by its expression as a function of R_g (19), one obtains:

$$S_{\infty}(q) = \underbrace{\frac{\beta \Lambda(q, \xi_{\infty}, D_{fi}, \beta)}{\Gamma\left(\frac{D_{fi}}{\beta}\right)}}_{B(q, \xi_{\infty}, D_{fi}, \beta)} \left[\frac{\Gamma\left(\frac{D_{fi}+2}{\beta}\right)}{2\Gamma\left(\frac{D_{fi}}{\beta}\right)}\right]^{D_{fi}/2}}_{B(q, \xi_{\infty}, D_{fi}, \beta)} (qR_g)^{-D_{fi}}$$
(21)

This corresponds to the asymptotic form of the structure factor in the powerlaw regime. A has an analytical expression in the particular case of infinitely large particles and for $0 < D_{fi} < 2$. This enables the expression of B to be written as:

$$B(q,\xi_{\infty} \to \infty, D_{fi},\beta) = \sin\left(\frac{\pi}{2}\left(D_{fi}-1\right)\right) \frac{\beta\Gamma\left(D_{fi}-1\right)}{\Gamma\left(\frac{D_{fi}}{\beta}\right)} \left[\frac{\Gamma\left(\frac{D_{fi}+2}{\beta}\right)}{2\Gamma\left(\frac{D_{fi}}{\beta}\right)}\right]^{D_{fi}/2}$$
(22)

This expression has been previously developed by Heinson et al. (2012) and before that by Nicolai et al. (1994). In these works however, the mathematical hypothesis $0 < D_{fi} < 2$ was not mentioned. Nevertheless, by comparing this analytical expression with a numerical solution, it seems that expression of ⁸⁵ *B* is correct for $0 < D_{fi} < 3$ at least if $\beta \leq 2.5$. It is interesting to observe ⁸⁶ that the power-law regime is not affected by polydispersity except if D_{fi} or β ⁸⁷ are intrinsically affected by the primary sphere polydispersity, as explained ⁸⁸ in the next section.

The novelty of the proposed approach is to provide a generalized expression for the structure factor (Eq. 20), which is valid for all numbers of primary spheres and takes into account the primary sphere polydispersity.

This advantage can be illustrated by observing the particular case of forward light scattering $(q \rightarrow 0)$ for an agglomerate consisting of monodisperse primary spheres. By applying a limited development of the functions in Eq. 20 and by using the definition of the radius of gyration, one can show that:

$$S(q \to 0) = \frac{V_p}{V_a} + \left(1 - \frac{V_p}{V_a}\right) \left(1 + \frac{q^2}{3} \frac{R_g^2 - \frac{V_p}{V_a} \frac{3}{5} R_p^2}{1 - \frac{V_p}{V_a}}\right)$$
(23)

For large agglomerates, the well known result $S(q \to 0) = 1 + \frac{(qR_g)^2}{3}$ related to the Guinier regime can be found but, if the number of primary spheres tends toward 1, the structure factor at q = 0 becomes constant and equal to 1. Equation 23 also allows the minimum number of primary spheres needed for the Guinier regime to becomes valid to be evaluated. Equation 20 can be used to answer the same question in the polydisperse case, for any scattering angle or wavelength.

99 3. Results

100 3.1. Determination of the model's parameters

In order to evaluate the parameters of the model, a statistical analysis 101 was conducted on Diffusion Limited Cluster Agglomerates (DLCA) made up 102 of mono- and polydisperse primary spheres. The code MCAC Morán et al. 103 (2020); Morán et al. (2020) has been used, forcing the agglomeration to stay 104 within the Epstein regime in order to generate standard DLCA morphologies. 105 The volume fraction was fixed at 1 ppm, temperature 1700 K and 1 atm of 106 pressure, the primary sphere median diameter at $D_{p,geo} = 80$ nm and $\sigma_{p,geo} =$ 107 1.45 for the case of polydisperse monomers. A total number of 27,342 and 108 24,150 agglomerates have been simulated for monodisperse and polydisperse 109 monomers respectively. The classical fitting of N_p vs R_q/R_{pv} by the fractal 110 law (1) enables (Fig. 6) the population fractal dimensions and prefactors to 111 be determined respectively $D_{fp} = 1.77$ and $k_{fp} = 1.58$ for monodisperse and 112

 $D_{fp} = 1.77$ and $k_{fp} = 1.69$ in the polydisperse cases. Those values are typical of DLCA generated fractal agglomerates Eggersdorfer and Pratsinis (2012); Bushell and Amal (1998).

Regarding the numerical computation of the pair correlation, most of 116 the studies in the literature only considered the position of the centers of 117 the spheres and not their volume. This makes some peaks in A(r) to ap-118 pear for distances $r \leq 4R_p$ Filippov et al. (2000); Lattuada and Ehrl (2009); 119 Lattuada et al. (2003). Additionally, the application of this method is com-120 monly limited to monodisperse point-touching monomers. A few studies have 121 attempted to calculate it for more complex morphologies, including the par-122 tial distance distribution function introduced by Bushell and Amal (1998) 123 and the volume-based pair correlation function introduced by Morán et al. 124 (2019). The latter is used in the present study because it has the advantage 125 of considering the contribution of primary particles and is not limited to the 126 specific primary particle size distribution, shape or level of overlapping be-127 tween monomers. The pair correlation function is then calculated based on 128 300 random orientations and 200 radial positions Morán et al. (2019). 129

Concerning the fitting process, for each agglomerate, the radii of the constituting primary spheres are known as well as the agglomerate volume (V_a) and radius of gyration (R_g) . The model is thus reduced to only four unknown parameters, namely D_{fi} , β , ξ_{∞}/R_g , ξ_0/R_{pv} . The necessity to search for D_{fi} or to impose it, is discussed in the next section. The normalized pair correlation is fitted with the following expression of the model which comes from Eq. 12 after replacing C by Eq.18:

$$\frac{A(r)}{V_{a}} = \frac{1}{N_{p}R_{pv}^{3}} \sum_{i}^{N_{p}} \left(R_{pi}^{3} - \frac{3}{4}rR_{pi}^{2} + \frac{r^{3}}{16} \right) + \frac{\varphi D_{fi}}{3} \left(\frac{r}{R_{pv}} \right)^{D_{fi}-3} \left(e^{-\left(\frac{r}{R_{g}}\frac{R_{g}}{\xi_{\infty}}\right)^{\beta}} - e^{-\left(\frac{r}{R_{pv}}\frac{R_{pv}}{\xi}\right)^{\beta}} \right)$$
(24)

The parameter φ in Eq. 24 is obtained from the agglomerate's volume by rewriting Eq. 13 which is :

$$\varphi = \left(V_a - \frac{\overline{V_p^2}}{\overline{V_p}} \right) \frac{3\beta}{4\pi D_{fi}} \frac{R_{pv}^{-3}}{\Gamma\left(\frac{D_{fi}}{\beta}\right) \left(\left(\frac{R_g}{\xi_{\infty}}\right)^{-D_{fi}} \left(\frac{R_g}{R_{pv}}\right)^{D_{fi}} - \left(\frac{R_{pv}}{\xi}\right)^{-D_{fi}} \right)}$$
(25)

Figure 1: Examples of normalized pair correlation functions (dots), the contribution of primary particles A_{pp} (dash-dotted line), the contribution of the agglomerate A_{agg} (dashed line) and the total fit (continous line). Figure (a) and (b) correspond to monodisperse and polydisperse ($\sigma_{p,geo} = 1.45$) primary particles, respectively. Chosen agglomerates consist of $N_p = 17$ (black color) and $N_p = 250$ (red color).

Four examples of pair correlation functions are presented by different 130 symbols in Fig. 1. The left half of the figure presents the fitting for two ag-131 glomerates made up of 17 and 250 monodisperse primary spheres respectively 132 whereas the right half reports the results for polydisperse primary spheres 133 $(\sigma_{p,qeo} = 1.45)$. The fit is very good in all studied cases, showing that the 134 assumption of a unique β holds for a correct fitting process. The model also 135 succeeds in taking into account, the hump present at the transition between 136 A_{pp} (dash lines) and A_{agg} (long dashed lines). It can be observed that the 137 contribution from primary particles A_{pp} is independent of N_p for monodis-138 perse monomers and slightly dependent of N_p for polydisperse monomers. 139 Also, A_{agg} shows a clear difference for small and large N_p . This dependence 140 is studied systematically in the following sections. 141

142 3.2. Mean individual fractal dimension D_{fi}

In Fig. 2, the individual monodisperse and polydisperse fractal dimensions as reported as a function of the number of primary spheres per agglomerate. A few error bars are added to represent the 95% interval confidence for illustration purposes but they are not shown everywhere to avoid cluttering the figure. Firstly, a variation of the individual fractal dimension at least up to $N_p \approx 30$ can be observed, even if for small agglomerates, the domain of the pair correlation function used for determining the fractal dimension is too

small to obtain a reliable result, as indicated by the large error bars at small 150 N_p . From this point of view, imposing D_{fi} to have its asymptotic value can be 151 considered without having significant impact on the quality of the fit. Since 152 there is a large dispersion of D_{fi} for a given number of primary spheres, the 153 difference between fractal dimensions for the monodisperse and polydisperse 154 cases does not appear to be significant, thus indicating that polydispersity 155 does not seem to significantly affect the individual fractal dimension. They 156 both have a common asymptotic value of 1.64. At first, it might appear 157 surprising to observe a lower asymptotic individual fractal dimension than 158 that observed in the population based fractal plot, typically equal to 1.77, 159 as indicated in the previous section. However, this difference between fractal 160 dimensions determined by population and individual approaches has already 161 been reported by Wozniak et al. (2012), who also found a lower individual 162 fractal dimension (1.66 for Diesel soot particles) by using a Box-Counting 163 method compared to $D_{fp} = 1.88$ obtained by using the classical fractal-law. 164 More recently Altenhoff et al. (2020) found an average asymptotic fractal di-165 mension ~ 1.61 for individual agglomerate (obtained also by Box-Counting) 166 for soot particles from premixed diffusion flames while the population one is 167 within the $D_{fp} = 1.70 - 1.82$ depending on the method used. An explanation 168 for this difference is suggested in this section. 169

In what follows, the pair correlation model fitting is systematically performed by considering two scenarios. First, by imposing D_{fi} to have its asymptotic value (dashed lines Fig. 2) and secondly, by letting the individual fractal dimension D_{fi} be free. In any cases however, D_{fi} is not imposed to be equal to D_{fp} as previously done by Heinson et al. (2012) since it clearly appears that it does not correspond to the asymptotic behaviour exhibited by Fig. 2.

177 3.3. The packing factor φ

The packing factor is not directly determined during the fitting process 178 but is used as a constraint (see Eq. 25). The corresponding dependence on 179 the number of primary spheres per agglomerate (see left-hand part of Fig. 3) 180 is found to be highly dependent on whether the fractal dimension is imposed 181 or left free. This factor quantifies the local compactness in the vicinity of 182 a given primary sphere whereas fractal dimension is the general, scale de-183 pendence of the compactness of the agglomerate. The imposed D_{fi} case is 184 considered in the following since it produces a monotonous increase of the 185 packing factor. In the monodisperse case, this parameter is found to increase, 186

Figure 2: Fitted individual D_{fi} as a function of the number of primary particles. Error bars correspond to the 95% confidence intervals.

tending towards an asymptotic value close to 1.0, which is larger than the 187 value proposed by Heinson et al. (2012) for large DLCA agglomerates (0.68). 188 However, it should be noted that the latter value was determined by the 189 authors by interpreting the product $\varphi \times D_f$ by considering $D_{fi} = 1.8$, thus 190 explaining the lower determination of the packing factor than in the present 191 study, as can be verified by examining Eq. 25. It should also be noted that, 192 unlike the aforementioned work, φ is not constant, indicating that the lo-193 cal compactness increases with agglomerate size. Because for point-contact 194 cluster-cluster agglomerates the only way to increase the local compactness 195 at the vicinity of the primary sphere is to increase the number of contacts be-196 tween spheres (coordination number), the main explanation of the observed 197 increase of the packing factor is the increase of the coordination number 198 (see Appendix B). This is certainly due to the fact that larger structures 199 present a larger accessible surface area for cluster collisions enabling a more 200 important local compactness the occur when the cluster is large. The present 201 result seems to indicate that local compactness can be further increased with 202

the primary sphere polydispersity (blue triangles tending to $\varphi \approx 1.4$) and the number of primary spheres necessary to reach an asymptotic value seems also to be increased. The continuous curves in the imposed fractal dimension case corresponds to purely empirical fittings that will be used in section 3.6.

Figure 3: Fitted packing factor and stretching exponent as a function of the number of primary particles. The error bars correspond to the 95% confidence intervals.

²⁰⁷ 3.4. The stretching exponent β

The stretching exponent is reported in the right-hand part of Fig. 3. 208 Whether the individual fractal dimension is imposed or not, β experiences a 209 strong decrease with the agglomerate size increase. For small agglomerates, β 210 tends towards β_0 (small scales) whereas it tends towards β_{∞} for large agglom-211 erates (domination of large scales). So, the right-hand part of Fig. 3 indicates 212 that the probability for finding a primary sphere, which corresponds to the 213 meaning of A(r), decreases more sharply for small structures than for larger 214 This is related to the increasing number of possible configurations ones. 215 for positioning a new primary sphere on the outer shell of an increasingly 216 large agglomerate. Unlike φ , an asymptotic behaviour is found for large N_p . 217 The corresponding asymptotic value is found to be larger for monodisperse 218 agglomerates ($\beta_{\infty} = 3.2$) than for polydisperse ones ($\beta_{\infty} = 2.6$). The poly-219 disperse value is in better agreement with Heinson et al. (2012) than the 220 monodisperse primary sphere case where they determined $\beta_{\infty} = 2.5$. Hein-221 son et al. (2012) have shown that β is correlated to the particle anisotropy 222 and fractal prefactor. Indeed, we will see that the fractal prefactor is also 223 increased in the polydisperse case. 224

225 3.5. Small ξ_0 and large ξ_{∞} scales characteristic size parameters

As explained in section 2, the agglomerate term A_{agg} of the pair corre-226 lation function is delimited by small ξ_0 and large ξ_{∞} scale size parameters. 227 Those parameters are presented respectively in the left- and right-hand parts 228 of Fig. 4 after being made dimensionless by the volume equivalent primary 220 radius R_{pv} and the radius of gyration R_g respectively. The former increases 230 with the agglomerate size, which can be explained by a numerical compen-231 sating effect due to the decrease of the β parameter. That increase is more 232 pronounced for polydisperse primary spheres than for monodisperse ones. 233 On the other hand, the dimensionless large scale cutoff parameter decreases 234 with the agglomerate size. This is mathematically explained by the decrease 235 of the β with N_p since ξ_{∞}/R_q is driven by β and D_{fi} for large agglomerates 236 (see Eq.19). It can be seen that the forcing of D_{fi} has a limited impact on 237 these two dimensionless parameters.

Figure 4: Fitted size parameters of the cutoff functions at small and large scales as a function of the number of primary particles. Error bars correspond to the 95% confidence intervals.

238

239 3.6. Application of the model to the determination of the fractal prefactor 240 and agglomerates structure factor

To summarize, independently of the number and the polydispersity of the primary spheres, the agglomerate volume (Eq. 13), radius of gyration (Eq. 15), individual prefactor (Eq. 16) and structure factor (Eq. 20) can be expressed as a function of D_{fi} , β , φ , ξ_{∞} , ξ_0 by the following set of equations:

$$\begin{cases} \xi = \left[\xi_{0}^{-\beta} + \xi_{\infty}^{-\beta}\right]^{-1/\beta} \\ N_{p} = \frac{\overline{R_{p}^{6}}}{\overline{R_{p}^{3}}^{2}} + \frac{\varphi D_{fi}}{\beta} \Gamma\left(\frac{D_{fi}}{\beta}\right) \left(\frac{\xi_{\infty}^{D_{fi}} - \xi^{D_{fi}}}{R_{p}^{D_{fi}}}\right) \\ R_{g}^{2} = \frac{3}{5} \frac{\overline{R_{p}^{8}}}{\overline{R_{p}^{3}}^{2}} \frac{1}{N_{p}} + \left(1 - \frac{\overline{R_{p}^{6}}}{\overline{R_{p}^{3}}^{2}} \frac{1}{N_{p}}\right) \frac{\Gamma\left(\frac{D_{fi}+2}{\beta}\right)}{2\Gamma\left(\frac{D_{fi}}{\beta}\right)} \frac{\left(\xi_{\infty}^{D_{fi}-2} - \xi^{D_{fi}+2}\right)}{\left(\xi_{\infty}^{D_{fi}-2} - \xi^{D_{fi}}\right)} \\ k_{fi} = N_{p} \left[\frac{3}{5} \frac{\overline{R_{p}^{8}}}{\overline{R_{p}^{3}}^{3/3}} \frac{1}{N_{p}} + \left(1 - \frac{\overline{R_{p}^{6}}}{\overline{R_{p}^{3}}^{2}} \frac{1}{N_{p}}\right) \frac{\Gamma\left(\frac{D_{fi}+2}{\beta}\right)}{2R_{pv}^{2}\Gamma\left(\frac{D_{fi}}{\beta}\right)} \frac{\left(\xi_{\infty}^{D_{fi}-2} - \xi^{D_{fi}+2}\right)}{\left(\xi_{\infty}^{D_{fi}-2} - \xi^{D_{fi}}\right)}\right]^{-\frac{D_{fi}}{2}} \\ S(q) = \frac{1}{N_{p}\overline{R_{p}^{3}}} \int_{0}^{\infty} 9R_{p}^{6} \frac{\left[\sin(qR_{p}) - qR_{p}\cos(qR_{p})\right]^{2}}{(qR_{p})^{6}} f_{pp}(R_{p})dR_{p} \\ + \left(1 - \frac{1}{N_{p}}\frac{\overline{R_{p}^{6}}}{\overline{R_{p}^{3}}^{2}}\right) \frac{\beta}{q^{D_{fi}}\Gamma\left(\frac{D_{fi}}{\beta}\right)} \frac{\Lambda(q,\xi_{\infty}, D_{fi},\beta) - \Lambda(q,\xi, D_{fi},\beta)}{\xi_{\infty}^{D_{fi}-2} - \xi^{D_{fi}}} \\ \Lambda(q,\xi, D_{fi},\beta) = \int_{0}^{\infty} (qr)^{D_{fi}-1} e^{-\left(\frac{r}{\xi}\right)^{\beta}} \frac{\sin(qr)}{qr} d(qr) \end{cases}$$

$$(26)$$

In what follows, in order to illustrate the modelling of the fractal prefactor and structure factor, equations 26 are considered along with the analysis of the parameters dependence on N_p based on the fitting process with D_{fi} imposed to 1.64 (plain curves in Figs. 3,4 and corresponding equations reported in Appendix A).

Figure 5 presents in fill symbols the solution of Eq. 26 for the modelling of 246 the individual fractal prefactor by considering $D_{fi} = 1.64$. The results show 247 that the individual fractal prefactor never reaches a plateau and a dependence 248 on N_p should be considered, in particular for polydisperse primary spheres 249 (red curve). But, even for the monodisperse case for which a asymptotic 250 value seems attainable, k_{fi} is still varying at N_p 's recommended by previous 251 studies Ehrl et al. (2009); Lazzari et al. (2016); Isella and Drossinos (2010). 252 The open symbols in Fig. 5 correspond to the application of the asymptotic 253 derivation proposed by Heinson et al. (2012) (Eq. 7) by considering the de-254 pendence of β and φ on N_p as reported in Fig. 3 and in Appendix A. There 255 is clearly a very good agreement with the present model for large agglomer-256 ates. The difference between both approaches is an indication of the influence 257 played by the cutoff at small scales and by taking into account, the primary 258 spheres self-intersection A_{pp} that represents the novelty of the present study. 259

Surprisingly, it appears that approximately 70 and 40 primary spheres respectively are necessary in the monodisperse and polydisperse case to make the influence of the small scales negligible. This shows the importance of taking into account small scale effects, in particular as most of particles have typical sizes in this range, such as soot particles that have an average number of primary spheres close to 100 Köylü and Faeth (1992); Yon et al. (2018); Sorensen et al. (1992b).

Figure 5: Application of the model to the determination of the individual fractal prefactor k_{fi} depending on the number of primary spheres.

Fig. 5 clearly reports larger k_{fi} for large agglomerates made of polydis-267 perse spheres compared to the monodisperse ones. This is related to the pre-268 viously observed larger packing factor, as depicted in the left half of Fig. 3. 269 As an illustration, the ratio between k_{fi} in polydisperse and monodisperse 270 cases is found to be 1.11 for $N_p = 100$, which is in good agreement with 271 the ratio of k_{fp} that is found to be 1.07. But, in addition to varying with 272 N_p , k_{fi} is found to be much larger than k_{fp} . This can also explain why the 273 population based fractal dimension $D_{fp} = 1.77$ is found to be larger than 274

275 $D_{fi} = 1.64.$

These findings are confirmed by Fig. 6, which presents the classical popu-276 lation based mass fractal plot for both monodisperse and polydisperse studied 277 agglomerates. The points correspond to each considered individual agglom-278 erate in the present study and the continuous red curves correspond to the 279 present model (with D_{fi} imposed at 1.64 and a variable k_{fi} reported in fig. 5). 280 It can be clearly seen that the model is in good agreement with the points 281 scatter. Also, the fitting of the model's curves by a classical fractal law pro-282 duces population based fractal parameters (equations in red in Fig. 6) in 283 good agreement with the ones determined from the points scatter and thus 284 with conventional values of D_{fi} and k_{fi} . This corroborates the observations 285 made by Wozniak et al. (2012), suggesting that the conventional fractal di-286 mension determined based on the fractal plot is not exactly representative 287 of the individual one expressed by the pair correlation function (or structure 288 factor as explained in the next section). This is explained by the important 289 role played by the cutoff functions making the agglomerate not really fractal 290 but "quasi-fractal". 291

Figure 7 presents the result of the modelling of the structure factor for 292 different values of N_p from 1 to 300 in the monodisperse (upper half) and the 293 polydisperse case (bottom half). The structure factors are multiplied by the 294 square of the agglomerate's volume because the scattered light intensity is 295 proportional to that product. It also enables the curves to be distinguished 296 graphically. The abscissa is the classical dimensionless form of the q param-297 eter by considering the radius of gyration of the agglomerate. The figure 298 illustrates the ability of the proposed model to evaluate the structure factor 299 of agglomerates independently of their size and taking polydispersity into 300 account. Indeed, the model reproduces the Porod's slope (-4) as illustrated 301 for $N_p = 1$ and corresponding oscillations in the monodisperse case. It is 302 also able to reproduce the Guinier and power-law regimes for $qR_q \leq 3$ and 303 $3 \leq qR_g \leq 30$ respectively as illustrated by the relatively good agreement 304 with the Dobbins and Megaridis structure factor Dobbins and Megaridis 305 (1991) for fractal agglomerates reported in the dashed green curves. Never-306 theless, unlike the Dobbins and Megaridis' structure factor (RDG-FA), the 307 current model enables the transition from power-law regime toward Porod's 308 regime at large q, to be determined. This is of interest in particular for the 309 interpretation of SAXS measurements since the range of q covered by X-rays 310 for nanoparticles usually contains this transition regime between power-law 311 and Porod's law. 312

Figure 6: Fractal Plots. Each dot corresponds to a given agglomerate, the continuous red curve corresponds to the proposed modelling.

In addition to the particle size determination, one of the most usual uses 313 of Static Light Scattering with visible light or SAXS with X rays, is the 314 determination of the local slopes in the log-log representation of the structure 315 factor in the power-law and Porod's law regimes, which provide $-D_{fi}$ for large 316 agglomerates and -4 for smooth primary spheres respectively. To discuss 317 this ability, the magnitude of the local slopes based on the proposed model 318 for the polydisperse case and different agglomerate sizes (N_p) is plotted in 319 Fig. 8. The dashed lines represent the expected values for the power-law 320 and Porod's law. The figure illustrates that particular care must be taken 321 when interpreting the local slopes for both discussed regimes. Indeed, even 322 for large agglomerates ($N_p = 300$ in the present case), oscillations can be 323 observed in the range qR_q between 3-30, where RDG-FA predicts a plateau 324

Figure 7: Application of the model to the determination of the structure factor dependence on the number of primary spheres. The upper shows the monodisperse primary spheres case, and bottom half, the polydisperse primary spheres case.

Figure 8: Opposite of the magnitude of the local slope of the modelled structure factor for different number of primary particles in polydisperse case.

equal to the fractal dimension. Consequently, it appears quite illusive to 325 accurately determine the fractal dimension based on a local fitting of the 326 structure factor for quasi-fractal agglomerates. It also appears in Fig. 8 that 327 to arrive at the Porod regime qR_g must be larger as the particle size grows. 328 Even if a Porod's law seems established for large qR_g in the bottom plot 329 of Figure 7, its fitting can provide different values than 4 even if particles 330 are perfectly smooth spheres in point contact. This is due to the strong 331 influence of the agglomerate structure A_{aqq} up to large q. Consequently, it is 332 important to be aware of this effect in order not to interpret this change of 333 slope as an indication of the primary sphere surface roughness as proposed by 334 Beaucage Beaucage (1995); Beaucage et al. (2004), even if this effect cannot 335 be excluded. Note that experimental measurements are smoothed due to the 336 polydisperse nature of the agglomerate population, that is not considered in 337 the present analysis. 338

339 4. Conclusions

Experimentally measured nanoparticle agglomerates are usually regarded 340 as fractal-like due to their finite size. In this context, their morphological 341 characterization usually involves the addition of a cut-off function Sorensen 342 (2001); Cai et al. (1995); Sorensen et al. (1992a); Nicolai et al. (1994); Hein-343 son et al. (2012). However, these morphological analyses are also limited 344 at small scales, particularly when approaching the monomer size scale. To 345 the author's knowledge, apart from the work carried out by Lattuada et al. 346 (2003), there are currently no models able to overcome this issue and there-347 fore, the present work is intended to cover this gap. This is achieved by 348 considering the contribution of the primary spheres in the modeling of the 349 pair correlation function as well as by adding a cutoff function at small scales. 350 This results in a more sophisticated modeling of the pair correlation based 351 on 5 parameters, namely the individual agglomerate's fractal dimension, the 352 packing factor, the stretching exponent and two characteristic size parame-353 ters representative of small and large scales plus a parameter describing the 354 primary sphere size distribution. In the limit of large agglomerates, the pro-355 posed method gives results in good agreement with previous work Ehrl et al. 356 (2009); Lazzari et al. (2016). 357

The dependence of the model parameters on agglomerate size has been investigated by computing the pair correlation functions of numerically generated DLCA agglomerates. Analytical expressions for the individual fractal prefactor and structure factor are also derived from the proposed model.

One important result is that the classical fractal law based on a popu-362 lation of agglomerates is not suitable for determining the individual fractal 363 dimension, due to the limitations in fractal geometry induced by both small 364 and large scales. Indeed, the fractal prefactor is shown to strongly evolve 365 with agglomerate size, thus resulting in an overestimation of the effective 366 population based fractal dimension (classically 1.77 for DLCA agglomer-367 ates) compared to the individual one (found to be 1.64 in the present study). 368 Consequently, the agglomerates have to be extremely large (constituted of a 369 very large number of primary spheres, more than 100) to avoid the bias in-370 duced by the finite size of the particle. Therefore, the present work highlights 371 the bias induced by small scales that is shown to be particularly important 372 when considering the polydispersity of primary spheres. Furthermore, it is 373 found that the local porosity (packing factor) also evolves with particle size. 374 The present work also enables the unified modelling of the structure fac-375

tor for quasi-fractal agglomerates to be carried out, regardless the number of 376 primary spheres and taking polydispersity into account. This work therefore 377 extends the field of validity of the RDG-FA model Sorensen (2001); Dob-378 bins and Megaridis (1991) and provides a theoretical basis for the scaling 379 approaches as proposed by Beaucage Beaucage (1995). Supplementing the 380 investigation by Lattuada et al. (2003), this work enables the modelling to 381 be carried out of the transition between Guinier and Power-law regimes as 382 well as between Power-law and Porod's law regimes. This approach is thus 383 a promising and complementary tool to the RDG-FA and Beaucage mod-384 els for the interpretation of visible or X-ray light scattering experiments for 385 agglomerates constituted of a limited number of primary spheres. 386

The aim of the present model is for the analysis of experimental TEM/SEM 387 images of nanoparticles agglomerates, especially at early stages of particle 388 formation where agglomerates consist of a few number of monomers Bescond 380 et al. (2014); Ouf et al. (2019). Indeed, correlations for agglomerates pro-390 jected areas, collision radius, etc. may be adapted to small agglomerates 391 based on the current model Brasil et al. (1999); Thajudeen et al. (2012). Also, 392 the numerical simulations of nanoparticle coagulation based on the popula-393 tion balance equation, lack models for agglomerates morphology ranging from 394 one monomer to large agglomerates Kostoglou and Konstandopoulos (2001). 395 The same problem is found for tunable algorithms where the uncertainty of 396 selecting constant fractal parameters during the agglomeration of particles 397 still exists Morán et al. (2019); Singh and Tsotsas (2020). The use of the 398 present model in tunable codes is promising in order to generate more realistic 399 morphologies, closer to those produced by Diffusion Limited particle-Cluster 400 Agglomeration Meakin (1999); Eggersdorfer and Pratsinis (2012). Future de-401 velopments of the proposed model should take into account, primary sphere 402 overlapping, more realistic morphologies and aggregates size polydispersity. 403

$$\Gamma(D_f/\beta) = 1.36 + \frac{1.54}{\ln N_p}$$
 (A.5)

$$\frac{\Gamma\left(\frac{D_{fi}+2}{\beta}\right)}{2\Gamma\left(\frac{D_{fi}}{\beta}\right)} = 0.31 - 0.19 \frac{\ln N_p}{N_p} \tag{A.6}$$

410 Appendix A.2. Polydisperse monomers

Based on the imposed fractal dimension $D_{fi} = 1.64$:

$$\beta = 2.496 + \exp\left(-0.739(\log(N_p) - 2.778)\right) \tag{A.7}$$

$$\frac{\xi_0}{R_{pv}} = \frac{3.448}{1 + \exp\left(-0.242(\log(N_p) - 2.587)\right)}$$
(A.8)

$$\frac{\xi_{\infty}}{R_g} = 1.554 + \exp\left(-0.481(\log(N_p) - 0.632)\right)$$
(A.9)

$$\phi = 1.840 - \exp\left(-0.220(\log(N_p) - 3.123)\right)$$
(A.10)

$$\Gamma(D_f/\beta) = 0.93 + \frac{2.26}{\ln N_p}$$
 (A.11)

$$\frac{\Gamma\left(\frac{D_{fi}+2}{\beta}\right)}{2\Gamma\left(\frac{D_{fi}}{\beta}\right)} = 0.37 - 0.39 \frac{\ln N_p}{N_p} \tag{A.12}$$

Figure B.9: Average coordination number as a function of the number of primary particles.
