ABSTRACT

Multispectral imaging systems are currently expanding with a variety of multispectral demosaicking algorithms. But these algorithms have limitations due to the remarkable presence of artifacts in the reconstructed image. In this paper, we propose a powerful multispectral image demosaicking method that focuses on the G band and luminance component. We've first identified a relevant 4-and 5-band multispectral filter array (MSFA) with the dominant G band and then proposed an algorithm that consistently estimates the missing G values and other missing components using a convolution operator and a weighted bilinear interpolation algorithm based on the luminance component. Using the considered MSFA patterns, we've also demonstrated that our algorithm outperforms existing approaches both visually and quantitatively in terms of the PSNR and SSIM.

1. Introduction

Multispectral images are made of more than three bands. The higher the number of bands, the more information that is available and the more useful the image is [1,2]. The MSFA imaging system is still a subject of considerable research and is still under development.

Multispectral image acquisition systems can be classified into three types [3]:

- multi-camera systems that capture images in a single shot using several cameras with different filters, thereby making the system quite complicated because a perfect alignment of several different cameras is required [4];
- single-camera multi-shot systems that capture images with a high spectral resolution but require multiple shots to obtain images with a high-speed lighting system for real-time imaging [5]; and
- single-camera systems that overcome the problems of the first two categories of systems in terms of size, cost, and real-time imaging [6–8]. Examples of the latter are RGB cameras equipped with one of Bayer's well-known color filter arrays (CFAs).

To capture multispectral images with a single image capture system, a multispectral filter array (MSFA) inspired by digital cameras featuring a Bayer CFA is required. Therefore, the use of a single camera system involves the design of MSFA-selective spectral filters arranged in a periodic mosaic defined by a basic pattern [2,7,9–13]. However, owing to the lack of a standard MSFA, as in the case of color images with a Bayer CFA, it is difficult to design an optimal MSFA and thus develop a powerful demosaicking algorithm. Several algorithms have been proposed in the literature [1,3,7,9,10,14–19] using different MSFAs and achieving an attenuated performance. Although the luminance component is important in an image, few algorithms have explicitly used it in their demosaicking process [18].

In this paper, we have identified a 4- and 5-band MSFA and proposed a luminance component-based multispectral demosaicking algorithm (LCBD) that estimates the missing G component at each pixel by applying a convolution method, and the other components missing at each pixel using a luminance component. This paper is organized as follows: In the second section, we review the multispectral imaging systems proposed in the literature, and in the third section, we describe the actual proposed algorithm. The results and discussion are presented in the fourth and fifth Sections respectively.

2. State-of-the-art demosaicking techniques for multispectral image

For the implementation of multispectral image demosaicking techniques, the design of an optimal MSFA and an efficient demosaicking

algorithm are two fundamental processes for the reconstruction of a full-resolution multispectral image that best limits the presence of artifacts. Several related proposals have been made in the literature.

2.1. Approaches to the design of the MSFA

Although Bayer's CFA was unanimously approved for use with color images, this is not the case with multispectral images. Numerous MSFA patterns have also been proposed [6]. For example, Miao et al. proposed a generic method for the design of MSFAs based on a binary tree, considering the probability of occurrence of each spectral band [10,14]. The MSFA is generated based on the number of spectral bands and their appearance probabilities. Many of the recently proposed MSFAs have been inspired by this generic method. In addition, Monno et al. [7] proposed a 5-band MSFA pattern based on the high-density requirement of the G-band, as with Bayer's CFA, and their proposal was applied by Jaiswal et al. in their multispectral demosaicking algorithm [20]. Bangyong et al. also proposed a 4-band MSFA pattern [18] with the same probability of occurrence for each band and a 9-band MSFA [19] in which one band is dominant and the other bands with equal probability of occurrence arranged in 4×4 patterns. Brauers and Aach [11] implemented a six-band MSFA in a 3×2 pattern to speed up the linear interpolation. Aggarwal and Majumdar proposed another simple MSFA by arranging four diagonally distributed filters [21] and then another random MSFA pattern [22], where each channel has the same probability of occurrence. Noting that the number of bands is inversely proportional to the spatial correlation, Shrestha et al. [23] proposed a particular MSFA pattern for a spectral reconstruction and estimation of the reflectance spectra. To find the best compromise between spatial and spectral resolution, Yasuma et al. designed a seven-band MSFA composed of three primary and four secondary color filters [12]. To overcome the difficulties in combining the spectral resolution and spatial correlation in multispectral imaging systems, Mihoubi et al. proposed a 16-band MSFA without dominant bands [2].

Several proposals have also been made for imaging systems involving the visible and near infrared (NIR) domains. Hershey and Zhang [24] designed a multispectral camera based on a 4-band MSFA with three color bands and a near-infrared band. Lu et al. [38] proposed an MSFA pattern as an optimization problem in the space domain by providing an iterative procedure to search locally for the optimal solutions. In addition, Kiku et al. [25] proposed a modified Bayer CFA pattern in which the additional fourth band was weakly sampled and arranged in a slightly tilted square grid. Indeed, their approach is based on the assumption that there is no correlation between the RGB and additional bands. The so-called Hybrid CFA still maintains a high density of the G band. Lapray et al. [6] defined two MSFA patterns with a periodic spatial distribution corresponding to two different approaches. One approach favors spatial information, and the other favors spectral information. For remote sensing applications, Mercier et al. [26] examined the usefulness of the design of an MSFA instantaneous sensor. These different MSFAs have been used in several multispectral demosaicking algorithms.

2.2. Review of the MSFA demosaicking algorithms

Demosaicking is one of the most delicate tasks in a multispectral imaging system. Numerous demosaicking algorithms have been proposed based on an extension of a classical CFA algorithm [27,28]. Miao et al. [9] proposed a generic multispectral demosaicking method that interpolates each missing band using edge correlation information. The method first determines the interpolation order of the different spectral bands, followed by the interpolation order of the pixel locations for each spectral band. Finally, an interpolation algorithm that uses the edge correlation information is applied. By exploring the spatial and spectral correlation information in an interpolation of the missing bands, Aggarwal et al. [29] proposed a linear demosaicking technique that applies linear filtering on a raw MSFA image with a kernel whose parameters are determined through training. In Ref. [12], the MSFA is composed of three primary and four secondary color filters, and a low-pass filter in the Fourier domain is used to reconstruct the primary color, whereas the principle of a constant channel difference and residual interpolation by means of the correlation between channels is exploited to reconstruct the secondary spectral bands. In Ref. [11], Brawers and Aach proposed a linear algorithm in which the conventional color difference is first smoothed. The authors initially compute the sparse channel difference for each spectral band, and a fully defined channel difference is then estimated at each spectral band through a convolution of the previous sparse channel difference with a low-pass filter, which is a smoothing operation. Finally, a weighted bilinear interpolation is applied to the channel difference estimated to obtain the band at each pixel. Mizutani et al. [39] proposed an improvement of Brawers and Aach's method by iterating the process a certain number of times depending on the neighborhood considered. The interpolation was then extended to a multispectral approach. Wang et al. [13] extended classical median filtering to MSFA demosaicking. The spectral response of the filtering is derived from the input vectors by estimating the missing value at one band with another value close to the same or another band. In Ref. [30], the authors extended a CFA method based on the discrete wavelet transform to multispectral demosaicking by estimating the low- and high-frequency components of the missing bands. Later, they proposed a generic MSFA demosaicking algorithm based on linear interpolation, which combines the linear minimum mean square error (LMMSE) technique and the residual interpolation method [31]. Monno et al. [3,7,16,17,32] also proposed a series of demosaicking algorithms for a 5-band MSFA with a dominant G-band with a probability of occurrence of 50%. The first of these algorithms [3] uses an adaptive kernel that is estimated directly from a raw MSFA image and applied to an adaptive Gaussian oversampling to generate a guide image from the G-band data. The technique of joint bilateral adaptive oversampling is applied to both the guide image and the data of each spectral band to obtain the reconstructed image. In Ref. [16], the authors improved this method by using a guide filter, which is an excellent structure preservation filter that performs a linear transformation of a given guide image to interpolate the missing bands. The authors used a residual interpolation to generate a guide image for a structure preserving interpolation [17] and proposed an adaptive residual interpolation by adaptively combining two algorithms based on residual interpolation and selecting an appropriate number of iterations for each pixel [32]. The authors then developed several guided images that were used in the interpolation of different bands [7]. Jaiswal et al. [20] also used the high-frequency component of the G-band to interpolate the other bands based on an inter-band correlation analysis. In addition, Mihoubi et al. [2] proposed a 16-band MSFA algorithm based on a pseudo-panchromatic image (PPI), which is estimated by applying an averaging filter to the raw image and then adjusted such that the PPI values are correlated. The difference between each available value of the adjusted raw image and PPI is calculated. The calculated local directional weights are then used to estimate the fully defined difference using an adaptive weighted bilinear interpolation. Each band is finally estimated by adding a PPI and the difference. In Ref. [33], the authors proposed a method that uses spatial and spectral correlations to estimate the missing bands. Recently, Amba et al. [34] extended the algorithm based on linear minimum mean square errors for RGB color to multispectral demosaicking by applying a linear operator that minimizes the mean square error between the reconstructed image and the original raw image. This linear operator multiplied by the MSFA image provides

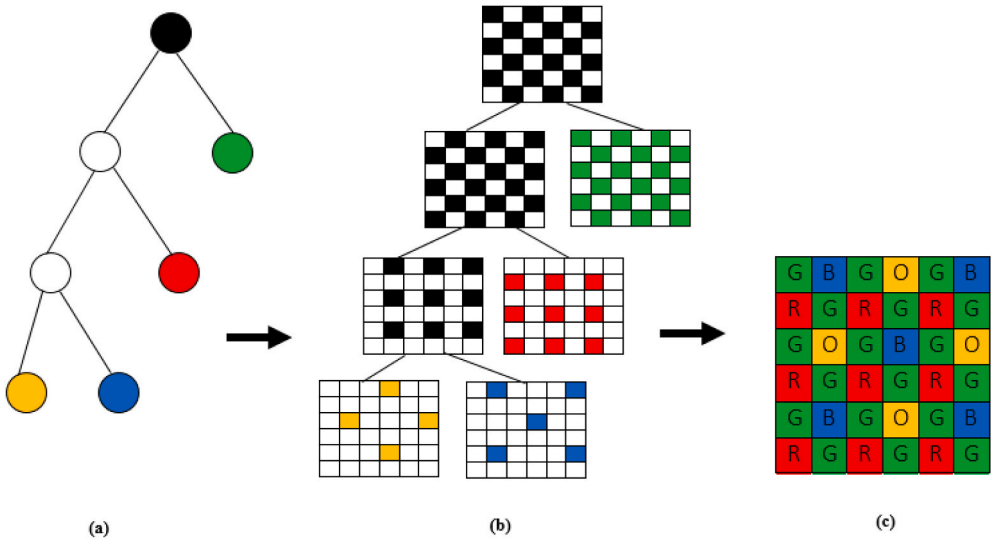

Fig. 1. 4-band MSFA configuration preceded by binary tree: (a) Binary tree considering appearance probabilities (b) Decomposition and subsampling processes (c) MSFA configuration.

an estimate of the reconstructed image. In Ref. [18], a method of applying directional interpolation along the edges of an image was proposed. In this method, the image edges are calculated from the raw image to define the direction interpolation with the neighbors. Considering the features of the filter arrays, image edges, and a constant hue, the missing bands per pixel were recovered from the existing bands. Then, the image is separated into high- and low-frequency components by applying a wavelet transform, and the high-frequency images that are highly correlated are modified using luminance information to refine the demosaicked image. In Ref. [19], a multispectral algorithm that estimates the missing dominant band at each spatial position with a weighted average of the neighboring values of the dominant band was described. The dominant band reconstructed at different spatial positions is then used as a guided image to estimate all other missing bands using the guided filter and a residual interpolation.

3. Proposed multispectral demosaicking system

3.1. Selected MSFA pattern

In multispectral single-sensor imaging, an increase in the number of spectral bands weakens the spatial correlation. To preserve the spectral coherence and spatial uniformity, we generate the MSFA using a generic method based on a binary tree [9,10,14,15]. With this method, the MSFA is generated by recursively dividing the checkerboard pattern based on a binary tree. The binary tree is defined by the number of spectral bands and the sampling densities of each spectral band, which are considered as parameters. The MSFA is formed by assigning each spectral band to the leaf of the binary tree.

In our case, for the 4- and 5-band MSFA patterns identified (see Figs. 1 and 2), we assigned higher sampling densities in the following order: G, R, and B–O for the 4-band MSFA and G, R-B-O-C for the 5-band MSFA, respectively. Table 2 shows the probability of the occurrence of spectral bands in each MSFA pattern.

3.2. Estimating multispectral luminance

A multispectral image is represented by an array of M rows, N columns, and P spectral channels. At each spatial location (x, y), several spectral components (S_p) are defined by

$$S_p(x,y) = \int_{\lambda} L(x,y,\lambda)\phi_p(\lambda)d\lambda \tag{1}$$

where $L(x,y,\lambda)$ is the spectrally dependent irradiance at each location, $\varphi_p(\lambda)$ is the spectral sensitivity function for a given sensor response (Fig. 3), and λ is the wavelength [6].

Let $I_{MSFA}(x,y)$ be a raw multispectral digital image from a single sensor. $I_{MSFA}(x,y)$ is a mosaic image with one channel per pixel and can be represented by

$$I_{MSFA}(x,y) = \sum_{p} S_p(x,y)Z_p(x,y) \tag{2}$$

where $\mathbf{Z_p}(\mathbf{x},\mathbf{y})$ are the orthogonal functions of dimension P and take values of 1 or 0 if channel p is present or not at the location $(\mathbf{x},\mathbf{y})$, respectively.

In frequency domain, referring to the MSFA in Ref. [18], an N-band single-sensor spectral imaging process raw data is expressed as follows:

$$I_{MSFA}(x,y) = \sum_{p} S_p(x,y)m_p(x,y) \tag{3}$$

where $m_p(x,y),\ (p = R,G,B,O,C)$ are the modulation functions at position (x,y) whose expressions depend on the MSFA pattern. Applied to our 4- and 5-band MSFA patterns chosen in Figs. 1(c) and 2(c), these modulation functions can be expressed as follows:

$$\begin{cases} m_R(x,y) = (1+\cos(\pi x))(1+\cos(\pi y))/4 \\ m_G(x,y) = (1+\cos(\pi x)\cos(\pi y))/2 \\ m_B(x,y) = (1-\cos(\pi x))(1+\cos(\pi y))/8 \\ m_O(x,y) = (1-\cos(\pi x))(1-\cos(\pi y))/8 \end{cases} \tag{4}$$

For 4-band MSFA

$$\begin{cases} m_R(x,y) = (1+\cos(\pi x))(1+\cos(\pi y))/8 \\ m_G(x,y) = (1+\cos(\pi x)\cos(\pi y))/2 \\ m_B(x,y) = (1-\cos(\pi x))(1+\cos(\pi y))/8 \\ m_O(x,y) = (1-\cos(\pi x))(1-\cos(\pi y))/8 \\ m_C(x,y) = (1+\cos(\pi x))(1-\cos(\pi y))/8 \end{cases} \tag{5}$$

For 5-band MSFA.

From equation (4) of 4-band MSFA, Eq. (3) becomes

$$I_{MSFA}(x,y) = \tfrac{1}{4}\left[R(x,y) + 2G(x,y) + \tfrac{1}{2}B(x,y) + \tfrac{1}{2}O(x,y)\right] + \tfrac{1}{4}\left[R(x,y) - \tfrac{1}{2}O(x,y)\right][\cos(\pi x) + \cos(\pi y)] + \tfrac{1}{4}\left[R(x,y) + 2G(x,y) - \tfrac{1}{2}B(x,y) + \tfrac{1}{2}O(x,y)\right]\cos(\pi x)\cos(\pi y) - \tfrac{1}{8}B(x,y)[\cos(\pi x) - \cos(\pi y)] \quad (6)$$

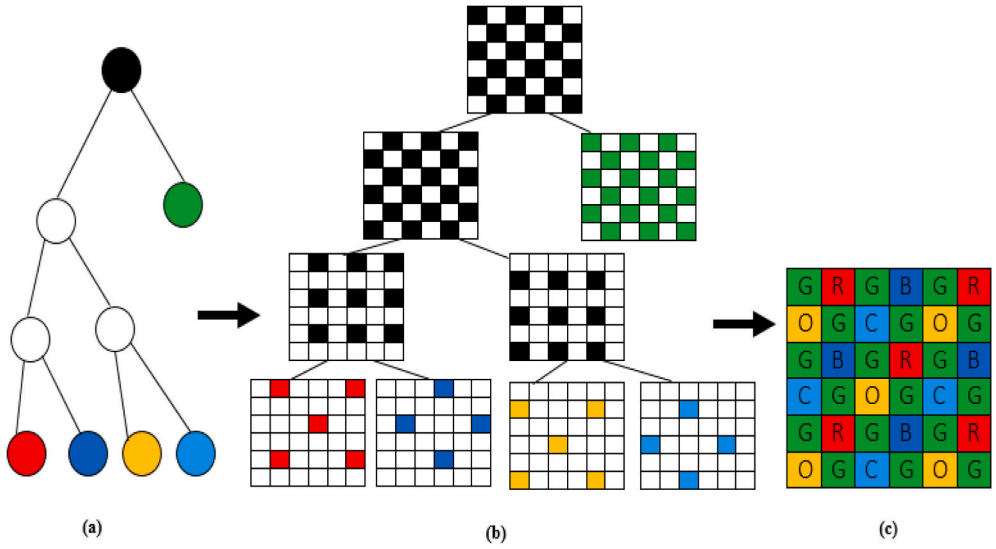

Fig. 2. 5-band MSFA configuration preceded by binary tree: (a) Binary tree considering appearance probabilities (b) Decomposition and subsampling processes (c) MSFA configuration.

Let consider the following transformation:

$$\cos(\pi x) = \cos(\pi(\mathrm{x} + \mathrm{y} - \mathrm{y})) = cos(\pi(\mathrm{x} + \mathrm{y}))\cos(\pi y) + \sin(\pi(\mathrm{x} + \mathrm{y}))\sin(\pi y) \quad (A)$$

Our MSFA pattern is such that the sum of the spatial coordinates x and y at G pixels in the MSFA image is even,

then,

$$cos(\pi(\mathrm{x} + \mathrm{y})) = 1\ ;\ \sin(\pi(\mathrm{x} + \mathrm{y})) = 0. \quad (B)$$

From (A) and (B), we have $\cos(\pi x) = \cos(\pi y)$. Therefore, at G pixels, Equation (6) becomes

$$I_{MSFA}(x,y) = \tfrac{1}{4}\left[R(x,y) + 2G(x,y) + \tfrac{1}{2}B(x,y) + \tfrac{1}{2}O(x,y)\right] + \tfrac{1}{4}\left[R(x,y) - \tfrac{1}{2}O(x,y)\right][\cos(\pi x) + cos(\pi y)] + \tfrac{1}{4}\left[R(x,y) + 2G(x,y) - \tfrac{1}{2}B(x,y) + \tfrac{1}{2}O(x,y)\right]cos(\pi x)cos(\pi y) \quad (7)$$

This equation can be separated into two parts through

$$I_{MSFA}(x,y) = \tfrac{1}{4}\left[R(x,y) + 2G(x,y) + \tfrac{1}{2}B(x,y) + \tfrac{1}{2}O(x,y)\right] + \sum_{S=R,G,B,O} S(x,y)\widetilde{m_S}(x,y) \quad (8)$$

Similarly, under the same conditions, the 5-band MSFA multispectral image can be written as

$$I_{MSFA}(x,y) = \tfrac{1}{8}[R(x,y) + 4G(x,y) + B(x,y) + O(x,y) + C(x,y)] + \tfrac{1}{8}[R(x,y) - O(x,y)][cos(\pi x) + cos(\pi y)] + \tfrac{1}{8}[R(x,y) + 4G(x,y) + O(x,y) - B(x,y) - C(x,y)]cos(\pi x)cos(\pi y) \quad (9)$$

and (9) can be separated into two terms as

$$I_{MSFA}(x,y) = \tfrac{1}{8}[R(x,y) + 4G(x,y) + B(x,y) + O(x,y) + C(x,y)] + \sum_{S=R,G,B,O,C} S(x,y)\widetilde{m_S}(x,y) \quad (10)$$

From equations (8) and (10), we obtain the following terms

$$L_{4\_MSFA}(x,y) = \tfrac{1}{4}\left[R(x,y) + 2G(x,y) + \tfrac{1}{2}B(x,y) + \tfrac{1}{2}O(x,y)\right] \quad (11)$$

$$L_{5\_MSFA}(x,y) = \tfrac{1}{8}[R(x,y) + 4G(x,y) + B(x,y) + O(x,y) + C(x,y)] \quad (12)$$

Equations (11) and (12) represent the luminance components at the G pixels, in the 4- and 5-band MSFA, and the other terms of equations (8) and (10) represent the chrominance components. In Ref. [35], a Gaussian low-pass filter with 11 × 11 support was used to estimate the luminance at each pixel of the CFA image. Lyan et al. [36] also showed the limitations of this filter and proposed a Gaussian low-pass filter with a 5 × 5 support to estimate the luminance at the G pixels of the CFA image because there is less overlap between the luminance and chrominance. Consequently, the complexity of the algorithm is reduced and the results are improved as much as possible. In our case, the condition of the spatial coordinates at G pixels reduces the overlap between the

luminance and chrominance components and can avoid artifacts in the reconstructed multispectral image. Thus, we use a Gaussian low-pass filter with a 5 × 5 support as in [36] to estimate the luminance component at the G pixels, and for other pixels, a Gaussian low-pass filter with 11 × 11 support as in [35]. The chrominance components were obtained by the color difference.

3.3. Proposed multispectral demosaicking algorithm

The algorithm is a multistep approach and first estimates the missing G components.

3.3.1. G component missing estimation

To consider the details at the edges, we used the convolution method to estimate the missing green components with a symmetric 3 × 3 low-pass filter according to equation (13). Let $\widehat{G}$ be the estimated G component at each pixel R, G, B, O, and C.

$$\widehat{G}(x,y) = \sum_{i=1}^{m}\sum_{j=1}^{n} g(i,j) f(x-i, y-j) \tag{13}$$

The convolution kernel g is a low pass filter defined as

$$g = 1/4 \begin{pmatrix} 0 & 1 & 0 \\ 1 & 4 & 1 \\ 0 & 1 & 0 \end{pmatrix} \tag{14}$$

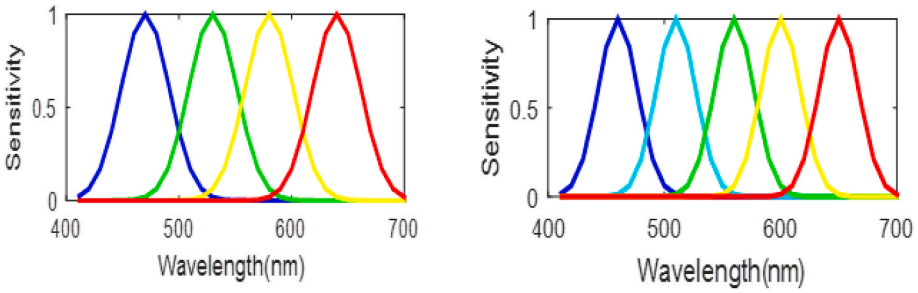

Fig. 3. Spectral sensitivity of the 4- (left) and 5-band (right) filters.

The matrix product f of $\breve{G}$ and I_{MSFA} allows an updating of the values of the different pixels at each spatial position before the convolution.

$$f(x,y) = \breve{G}(x,y) I_{MSFA} \tag{15}$$

The subsampling $\breve{G}$ of G band is obtained from MSFA (Figs. 1(c) and 2(c)) by filling in each G pixel with a 1 the other pixels by zero:

$$\breve{G}(x,y) = \begin{cases} 1 \text{ in G pixel} \\ 0 \text{ otherwise} \end{cases} \tag{16}$$

3.3.2. Other channels estimation at G pixels

After estimating the missing green bands at different pixels, each missing component, R, B, O, and C, at G pixels is determined through a bilinear interpolation of the color difference $R - \widehat{G}$, $B - \widehat{G}$, $O - \widehat{G}$, and $C - \widehat{G}$, respectively.

Referring to the 4-band MSFA (Fig. 1(c)), G pixels have red (R) neighbors in the horizontal or vertical direction. Therefore, we estimate R using

$$R(x,y) = \begin{cases} G(x,y) + \tfrac{1}{2}\left(R(x,y-1) - G(x,y-1) + R(x,y+1) - G(x,y+1)\right) \textit{ if } G \textit{ has } R \textit{ horizontal neighbors} \\ G(x,y) + \tfrac{1}{2}\left(R(x-1,y) - G(x-1,y) + R(x+1,y) - G(x+1,y)\right) \textit{ if } G \textit{ has } R \textit{ vertical neighbors} \end{cases} \tag{17}$$

Moreover, the G pixels have similar B and O neighbors in the horizontal and vertical directions. Therefore, B and O were estimated in the same manner. In the horizontal direction, they occupy either $(x, y-1)$, $(x, y+3)$ positions (first possibility), or $(x, y-3)$, $(x, y+1)$ positions (second possibility). Next, we estimate B as follows:

$$B(x,y) = \begin{cases} G(x,y) + \tfrac{1}{2}\left(B(x,y-1) - G(x,y-1) + B(x,y+3) - G(x,y+3)\right) \textit{ for the first possibility } y \textit{ positions} \\ G(x,y) + \tfrac{1}{2}\left(B(x,y-3) - G(x,y-3) + B(x,y+1) - G(x,y+1)\right) \textit{ for the second possibility } y \textit{ positions} \end{cases} \tag{18}$$

In the vertical direction, B is estimated in the same way by inverting the index order.

For a 5-band MSFA (Fig. 2(c)), the same strategy is used to estimate the R, B, O, and C bands in the G pixels.

3.3.3. Remaining missing components estimation

The other missing components R, B, O and C at the pixels C, O, B and R are estimated by the weighted sum of the color differences, where the weights are calculated on the basis luminance components according to the following steps:

3.3.3.1. Multispectral luminance $\widehat{L}(x,y)$ estimation. We estimate the luminance component $\widehat{L}(x,y)$ at different pixels according to the methods described in section 3.2.

*3.3.3.2. **Weight** calculation.* The estimated luminance $\widehat{L}(x,y)$ is decomposed using a low-pass filter normalized as $H_0 = 1/8\,[1\ 3\ 3\ 1]$ and its transpose H_0' into the horizontal $\widehat{L}_{HL}(x,y)$ and vertical $\widehat{L}_{LH}(x,y)$ components, unlike the wavelets used in our previous article [27].

We calculated the energies of $\widehat{L}_{HL}(x,y)$ and $\widehat{L}_{LH}(x,y)$, denoting them as $e_{HL}(x,y)$ and $e_{LH}(x,y)$, respectively, and used them to compute the horizontal and vertical weights at each pixel:

$$w_h(x,y) = \frac{F^* e_{HL}(x,y)}{F^* e_{HL}(x,y) + F^* e_{LH}(x,y)} \tag{19}$$

$$w_v(x,y) = \frac{F^* e_{LH}(x,y)}{F^* e_{HL}(x,y) + F^* e_{LH}(x,y)} \tag{20}$$

where F is a spatial averaging kernel of 3×3 size.

$$F = 1/9 \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix} \tag{21}$$

The energies $e_{HL}(x,y)$ and $e_{LH}(x,y)$ are calculated as

$$e_{HL} = \left|\widehat{L}_{HL}\right|^2 \qquad e_{LH} = \left|\widehat{L}_{LH}\right|^2 \tag{22}$$

The red samples in the blue locations were estimated as follows:

$$\widehat{R}(x,y) = B(x,y) + \frac{w_h(x,y)}{2}\left(\widehat{D}_{RB}(x-1,y) + \widehat{D}_{RB}(x+1,y)\right) + \frac{w_v(x,y)}{2}\left(\widehat{D}_{RB}(x,y-1) + \widehat{D}_{RB}(x,y+1)\right) \tag{23}$$

where:

$$\widehat{D}_{RB}(x,y) = \widehat{R}(x,y) - \widehat{B}(x,y) \tag{24}$$

The same strategy was applied to reconstruct the blue component in the red locations. This was the same for the other components. A block diagram of the proposed algorithm is shown in Fig. 5.

4. Results

In our experiments, we've used 15 images from a cave dataset [37], in which multispectral images consist of 31-band acquired under illuminant D65. The 31-band images were acquired every 10 nm between 400 and 700 nm. The images have the size of 512 × 512 pixels. The CAVE dataset is often used as a standard multispectral image dataset.

To evaluate the performance of the proposed algorithm, we've compared it with recent 4-band multispectral demosaicking methods, namely inter-band bilinear interpolation (IBBI) [28], generic binary tree edge sensing (BTES) [9], learned interpolation weights (LIW) [29], and directional filtering and wavelet transformation (DFWF) [18]. In the case of 5-band multispectral demosaicking methods, the comparison is done using the demosaicking algorithm based on adaptive spectral-correlation demosaicking (ASCD) [20], Practical One-Shot multispectral demosaicking (POS) [7], the BTES method [9], a guided filter (GF) [16], linear interpolation (LI) [31], and the iterative intensity difference (IID) [33].

4.1. Visual performance evaluations

For evaluation purposes, we've selected the statue, bead, and sponge images from the cave dataset. Figs. 6–8 show the results of the visual comparison of repectively the R band of the image *statue, the G band of the image bead* and the O band of the image *sponge* for different algorithms.

4.2. Quantitative performance evaluations

To quantitatively assess the objective performance of the proposed 4- and 5-band MSFA algorithms, we've used the peak signal-to-noise ratio (PSNR) and the structural similarity index (SSIM) metrics [18,31].

The average results we've obtained with our proposed algorithm are recorded in Tables 3 and 4 for the 4-band MSFA and in Tables 5 and 6 for the 5-band MSFA.These results are compared to the ones provided in [20]. ***The hight scores are in bold.***

5. Discussion

The fundamental problem of most of existing work in the literature on demosaicking multispectral images is the notable presence of artifacts in the reconstructed image. The mission is therefore to find an optimal algorithm to overcome these limits. In Fig. 6, the images reconstructed by the different comparison algorithms appear sharper than those of the original image, but are highly noisy. The BTES, LI, and POS methods show an edge degradation; however, such problems are reduced with the GF, ASCD, and IID methods. The image reconstructed using the proposed method has almost the same sharpness as the original image, but with almost no edge distortion or blurring. As it can be seen in Fig. 7, the BTES and LI methods exhibit severe edge distortion and blurring. These distortions are also visible with the ASCD method but are less accentuated. With the GF, POS, and IID methods, blurring was noticeable. Our method presents slight edge distortions, but with an almost complete absence of blurring. With Fig. 8, we see that the image reconstructed by the GF method appears sharper than the original image but with artifacts, whereas the image reconstructed by the ASCD method is less sharper but retains the edges. With the BTES, LI, and POS methods, the reconstructed images show artifacts, and the result is extremely unclear. Similarly, the performance of the IID method is insufficient compared with our approach in terms of the reconstructed image. By contrast, the image reconstructed by the proposed algorithm contains fewer distortions, and the result is clearer. Clearly, the same behavior was observed for the B and C bands.

According to the results in Table 3, our proposed 4-band MSFA algorithm outperformed the other methods for 10 out of 15 images used in the Cave dataset in terms of the PSNR, achieving the best average PSNR value. This one is followed by the DFWF method, which shows good scores for five of the images. In Table 4, according to the SSIM values, our method presents better results with five images and the best average SSIM value, followed by the BTES method, which presents good results with six images but a lower mean SSIM value than our approach. In general, the 4-band MSFA method proposed in this study is better than all other methods in terms of both the PSNR and SSIM.

In Tables 5 and 6, our algorithm outperformed the others on three bands, i.e., G, B, and O, in terms of the PSNR, but with a slightly lower mean value, compared to the ASCD method. This can be explained by the fact that the convolution technique used to estimate the dominant band considers the details of the edge where the inter-channel correlation is sufficiently high, which is not the case for the other bands, notably, the C band. However, in terms of the SSIM, the proposed method outperformed all other approaches. Globally, our algorithm has a better visual and objective performance compared to the other methods.

6. Conclusion

In this paper, we've proposed a multispectral demosaicking algorithm that exploits a convolution method to estimate the G-band and the luminance component to estimate the other missing bands. We've generated the MSFA with the required density in the G-band using the generic Benary tree method. To extract the luminance component at the green pixels, we've used a 5×5 Gaussian low-pass filter, and for the other components we've applied an 11×11 Gaussian low-pass filter. The results of the tests carried out show that our proposed algorithm is more powerful than the existing approaches, both visually and in terms of objective measurements. In our future work, we will study the application of these results in areas such as agriculture, medicine, and other fields. Extensive studies will be undertaken to provide a general extension of the proposed algorithm to more than five image bands. In addition, the MSFAs upon which our study is related are rectangular, and we plan to explore the efficiency of hexagonal MSFAs.
